Scoring a recommender's model of you on calibration, not recall

Muhammad Bilal[1,2] and João V. Graça[1]

1 Recall misses invented preferences

A profile that invents a preference misleads the recommender on every later suggestion. Recall tests can't see it.

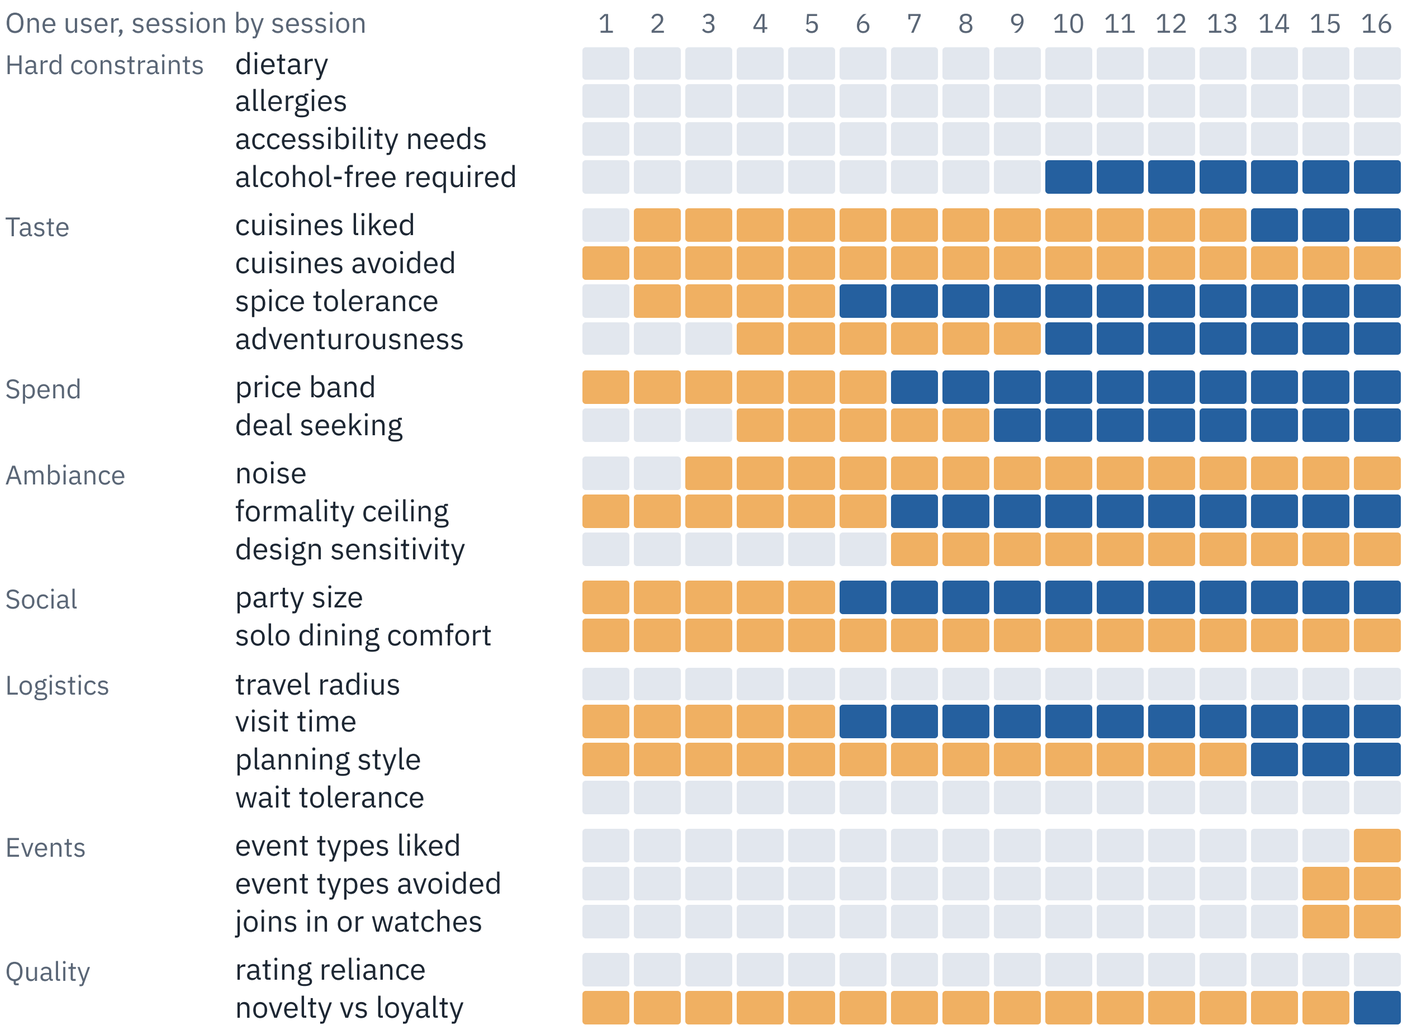

We score **calibration**: commit only where the conversation gives grounds, abstain everywhere else.

"Looking for somewhere to eat tonight, just me. [...] I just don't want to be crossing the whole city for it."

- **Weak:** travel radius
- **No evidence:** spice tolerance (true value: `seeks_hottest`)

Writing `seeks_hottest` now is right, and still a fabrication.

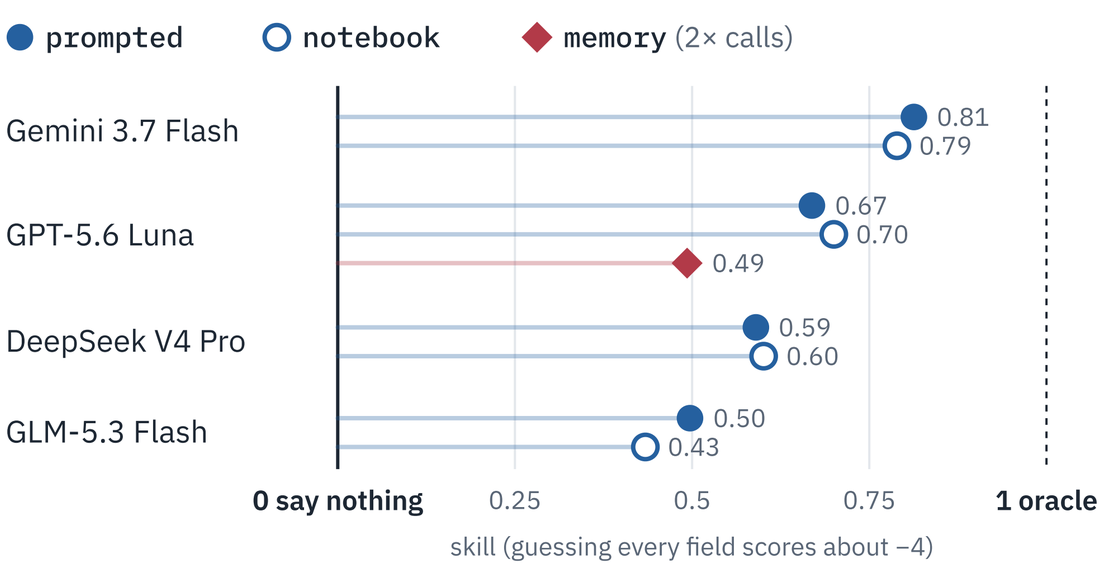

2 The evidence map: what could a careful reader know so far?

50 synthetic users, 612 chat sessions, 24 profile fields. A system reads one new session at a time and fills in the profile, or writes **unknown**.

	Commit	Abstain
Strong	scored by match	miss, 0
Weak	scored by match	5/6 credit
No evidence	**fabrication, −1**	correct, 0

3 Simple extractors calibrate well

- Switching the model moves skill over 5× more than switching **`prompted`** for **`notebook`**.
- The memory layer scores lower at twice the calls.

4 Main failure: committing too early

- Half to three-quarters of mistakes are guesses made before any evidence. The guess is right at most 17% of the time.
- The guess is usually the middle of the scale: "notices value", "fine with lively".
- Every model trips on the same cues: "a proper table rather than perching" becomes the hard constraint **`seating_required`**.
- The memory layer also loses what it knew: errors flicker wrong, right, wrong.

Score whether a profile knows when it doesn't know.

Committing before the evidence arrives is the main failure.

Simple single-pass extractors beat a memory layer here.

Limits. Synthetic data, one domain (dining). We score the profile, not the recommendations.
